OS-Specific Library	34

General Syntax

The file extension `.wiz` is suggested for code files.

The file extension `.wh` is suggested for header files.

Space, tab, and newline are considered whitespace.

Blocks begin with an opening curly brace.

Blocks end with a closing curly brace and do not require a semicolon.

All other statements require a semicolon.

Valid names (variable, function, and label) must contain at least one character that is not 0-9, and can include the characters A-Z, a-z, 0-9, and underscore.

Valid names cannot begin with 0x, 0b, or 0B.

Names are case sensitive.

Values are decimal by default. To use a hexadecimal value, add 0x with no whitespace before the hexadecimal digits. To use an octal value, add 0 with no whitespace before the octal digits. To use a binary value, add 0b or 0B with no whitespace before the octal digits.

Strings are treated as one if placed next to each other without an operator.

To call a function, place an opening and closing parenthesis after a variable or value and place the arguments between the parentheses.

Without being cast, the type of numerical values in front of a function call are assumed by what the function return value is assigned to and what arguments are provided.

Namespaces are defined in shards meaning that after defining a namespace, subsequent definitions of that namespace are allowed and added on to the first.

Namespace shards are not evaluated after being put together, but are evaluated individually. Outside the namespace, the namespace name and operator are appended to any non-private functions and variables.

Namespace shards do not have to use the namespace name and operator to address functions and variables in the current shard or other namespace shards of the same name. However, functions and variables outside the namespace are given precedence. To ensure the use of the functions and variables defined and/or declared in the current namespace, prefix the namespace name and operator to the function or variable name.

Variables

Variables are declared like so:

```
<type> <name>
```

Variables can be defined by adding an equal sign and the value like so:

```
int myint = 123;
```

Assigning to a previously declared or defined variable is the same but without the type.

To define a structure type, use the `struct` or `structure` statement like so:

```
struct mystructtype {  
    int num1,  
    int num2,  
    int num3  
}
```

Structure variables can be defined the same way as regular variables except the `struct` or `structure` keyword is used to enclose the structure definition name and the values are placed in a block and separated by commas like so:

```
struct(mystructtype) mystruct = {123, 456, 789};
```

The number of values given cannot exceed the number of elements in the structure.

Assigning to a structure is the same but without the type.

Structures can also be assigned to like so:

```
mystruct = {.num1 = 246, .num3 = 357};
```

Or:

```
mystruct.num2 = 159;
```

Arrays can be defined using square brackets and assigned to the same ways as structures:

```
int[3] myarray = {123, 456, 789}
```

Place the size of the array between the brackets. A size of zero is invalid.

To get an element from a structure pointer, place a dollar sign after the variable name:

```
mystruct$.num1 = 124;
```

To declare or define an array, place square brackets and the number of elements after the type name like so:

```
int[3] myarray;  
int[3] myarray2 = {1, 2, 3};
```

Values are placed in a block and separated by commas. The number of values should not exceed the number of elements in the array.

Multiple array dimensions can be declared or defined like so:

```
int[2][3] myarray;  
int[2][3] myarray2 = {{1, 2, 3}, {4, 5, 6}};
```

This will multiply the array size.

Pointers can be declared or defined by placing a dollar sign after the type name like so:

```
int$ mypointer;  
int$ mypointer2 = 123;
```

To get a pointer to a variable, put a dollar sign in front of the variable name like so (equivalent to `&myvar` in C):

```
$myvar
```

To get data at a pointer, put a dollar sign after the variable name like so (equivalent to `*myvar` in C):

```
myvar$
```

Multiple dollar signs can be added to help in the case of a multi-level pointer.

Pointer and array suffixes can be used together.

Make an array of 5 pointers to integers like so:

```
int[5]$ myvar;
```

Make a pointer to an array of 5 integers like so:

```
int$[5] myvar;
```

Functions

Functions are declared like so:

```
<type> <name> (<arg type> <arg name>)
```

Arguments are separated by commas

To declare a function to be defined later, add a semicolon like so:

```
int main(int, char$$);
```

As shown above, the variable name is optional.

Function declaration is optional as a function definition also counts as a declaration.

You can declare a function multiple times.

To define the function, add an opening curly brace, place your code, and end if with a closing curly brace like so:

```
int main(int argc, char$$ argv) {  
  
}
```

The variable name is mandatory when defining a function.

You can only define a function once.

Declare and define a variadic function like so:

```
void putFString(char$, ...);  
void putFString(char$ format, ...) {  
  
}
```

The three periods indicate that the function is variadic and accepts any number of arguments.

No more arguments should be defined after the three periods.

Namespaces

Namespaces are declared like so:

```
namespace <name> {  
    [statements]  
}
```

Anything you define in a namespace will have the namespace name and a period put before it.

Namespaces can be nested like so:

```
namespace test {  
    int a_var;  
    namespace my_ns1 {  
        int my_var;  
        void set_var(int val) {  
            .my_var = val;  
            ..a_var = val;  
        }  
    }  
    namespace my_ns2 {  
        int my_var;  
        void set_var(int val) {  
            test.my_ns2.my_var = val;  
            test.a_var = val;  
        }  
    }  
}
```

To set a variable in a namespace, you can either use the name, use a period with no namespace name, or use the namespace tree. Using more than one period and no namespace name will go up one level for each extra period provided.

In the case a namespace needs to access something with the same name as something else defined in the namespace, `global` can be used to start from the global scope or periods can be used to go past the highest namespace.

```
int var;  
namespace test {  
    int var;  
    void test(int val) {  
        global.var = val;    # sets global var  
        ..var = val;        # sets global var  
        .var = val;         # sets local var  
        var = val;          # sets local var  
    }  
}
```

Operators:

Logical operators will cast the conditions being tested to bool.

Assignment and Arithmetic		
=	var = val	Assign.
?	? (cond) {val1, val2}	Ternary operator. Resolves to val1 if cond is true and val2 if cond is false.
+	val1 + val2	Add.
++	++[+...]var var++[+...]	Increment before return if placed before variable name and increment after return if placed after variable name. Extra plus symbols may be added to increase the number of increments.
+=	var += val	Add val to var.
-	val1 - val2	Subtract.
--	--[-...]var var--[-...]	Decrement before return if placed before variable name and decrement after return if placed after variable name. Extra minus symbols may be added to increase the number of decrements.
-=	var -= val	Subtract val from var.
*	val1 * val2	Multiply.
*=	var *= val	multiply val by var.
/	val1 / val2	Divide.
/=	var /= val	Divide val by var.
%	val1 % val2	Modulus.
%=	var %= val	Assign the modulus of var, using val, to var.

Comparison		
==	val1 == val2	Equal to.
>	val1 > val2	Greater than.
<	val1 < val2	Less than.
>=	val1 >= val2	Greater than or equal to.
=>	val1 => val2	
<=	val1 <= val2	Less than or equal to.
=<	val1 =< val2	
!=	val1 != val2	Not equal.
<>	val1 <> val2	

Logical		
&&	cond1 && cond2	Logical AND.
	cond1 cond2	Logical OR.
^^	cond1 ^^ cond2	Logical XOR.
!	!cond	Logical NOT.

Bitwise		
&	val1 & val2	Bitwise AND.
	val1 val2	Bitwise OR.
^	val1 ^ val2	Bitwise Exclusive OR.
~	~val	Bitwise NOT.
<<	val1 << val2	Left shift.
>>	val1 >> val2	Right shift.
<<<	val1 <<< val2	Left rotate.
>>>	val1 >>> val2	Right rotate.

Data		
\$	\$var var\$	Returns a pointer when placed before a function, variable, or value name. Returns the data at a pointer when placed after a variable that is a pointer.
.	namespace.var struct.var {.var = val}	Access namespace and structures. Place after a namespace or structure name to access functions and variables of that namespace or elements of that structure. If used in curly brackets in the format of .<name> = <val> being assigned to a struct, only the names specified are assigned (for example, mystruct = {.data1 = 123, .data3 = 789} will only assign to data1 and data2 of mystruct).

Types:

Modifier prefixes and suffixes must be added without whitespace while behavior prefixes must be added with whitespace.

Base types	
<code>void</code>	Invalid if used to declare a variable and means no return value if used to declare a function.
<code>int</code>	Integer (32-bit signed by default).
<code>iptr</code>	Pointer-sized signed integer.
<code>uptr</code>	Pointer-sized unsigned integer.
<code>char</code>	8-bit integer (signed by default).
<code>float</code>	Floating point number (32-bit by default).
<code>bool</code>	Boolean (32-bit by default). This should not be used without a prefix in modular code such as libraries due to the possibility of a size difference.
<code>i8</code>	Signed 8-bit integer.
<code>i16</code>	Signed 16-bit integer.
<code>i32</code>	Signed 32-bit integer.
<code>i64</code>	Signed 64-bit integer.
<code>u8</code>	Unsigned 8-bit integer.
<code>u16</code>	Unsigned 16-bit integer.
<code>u32</code>	Unsigned 32-bit integer.
<code>u64</code>	Unsigned 64-bit integer.
<code>f32</code>	32-bit floating point number.
<code>f64</code>	64-bit floating point number.

Optional types	
<code>i24</code>	Signed 24-bit integer.
<code>i48</code>	Signed 48-bit integer.
<code>i128</code>	Signed 128-bit integer.
<code>i256</code>	Signed 256-bit integer.
<code>u24</code>	Unsigned 24-bit integer.
<code>u48</code>	Unsigned 48-bit integer.
<code>u128</code>	Unsigned 128-bit integer.
<code>u256</code>	Unsigned 256-bit integer.
<code>dec32</code>	32-bit decimal floating point number.
<code>dec64</code>	64-bit decimal floating point number.
<code>f16</code>	16-bit floating point number. If this is available, the <code>s</code> prefix should make <code>float</code> 16-bit.

Modifier prefixes	
<code>u</code>	Makes <code>int</code> and <code>char</code> unsigned and is invalid on other types.
<code>l</code>	Does not effect <code>int</code> on 32-bit architectures, makes <code>int</code> 64-bit on 64-bit architectures, makes <code>float</code> 64-bit, forces <code>bool</code> to be int-sized and is invalid on other types.
<code>ll</code>	Makes <code>int</code> 64-bit, makes <code>float</code> 64, 80, or 128-bit dependent on architecture, and is invalid on other types.
<code>s</code>	Makes <code>int</code> 16-bit, forces <code>bool</code> to be char-sized, and is invalid on other types.

Modifier suffixes	
!	Makes the type volatile at the point it is used (<code>int!\$</code> would be a volatile pointer to an <code>int</code> , <code>int\$!</code> would be a pointer to a volatile <code>int</code> , and <code>int!\$!</code> would be a volatile pointer to a volatile <code>int</code>).
\$	Makes any type a pointer to data of that type and can be used on <code>void</code> to make it a pointer to any type. Repeating will increase the pointing depth (<code>\$\$</code> is a pointer to a pointer, <code>\$\$\$</code> is a pointer to a pointer to a pointer, etc.)
%	Makes the data constant at the point it is used (<code>int%\$</code> would be a constant pointer to an <code>int</code> , <code>int\$%</code> would be a pointer to a constant <code>int</code> , and <code>int%%\$%</code> would be a constant pointer to a constant <code>int</code>). Attempting to assign to constant data will generate an error. This should only be used when the data is in a location that is not writable (<code>.rodata</code> for example).
[]	Makes any type a pointer to an array and can be used on <code>void</code> if not used as the last modifier suffix. A number can be specified inside to specify the array size. The number will be cast to an unsigned integer of machine address bus size. If a number is not given, it is invalid to use another array suffix directly after without a number (<code>int[] [5] [3]</code> is valid, <code>int[] [5] []</code> is not).

Special types	
func	<p>Defines a function pointer with a certain return value and arguments. Variadic function pointers can be defined by three periods after the last non-optional argument type. If no return type or argument types are given, the type should be handled as a callable <code>void\$</code> and assumed to take any amount of arguments with any types.</p> <p>Syntax: <code>func[:<return type>([argument types])]</code></p> <p>Examples: <code>func:int(int, char\$)</code> <code>func:int(char\$, ...)</code></p>
asm	<p>Invalid if used to declare a variable and makes it so a function's code is to be written in assembly. Syntax names are defined by the compiler. The default syntax is also compiler-specific. For assembly code that interferes with Wizardry's characters, place the code inside quotes instead of curly braces and end with a semicolon.</p> <p>Syntax: <code>asm:<return type>:[optional asm syntax]</code></p> <p>Example: <code>asm:void test() {</code> <code> mov %eax, 1</code> <code> mov %ebx, 2</code> <code>}</code> <code>asm:void test2() "\</code> <code> mov %eax, 1\n\</code> <code> mov %ebx, 2\</code> <code>";</code></p>

Keywords:

All program flow keywords are only valid inside of functions unless specified otherwise.

Program Flow		
break	<code>break;</code>	Exits the current <code>do</code> , <code>for</code> , or <code>while</code> block, or exits a case statement.
namespace	<code>namespace <name> { [statements] }</code>	Defines a namespace shard appending the namespace name and operator to all functions or variables defined inside. Is only valid in the global scope.
continue	<code>continue;</code>	Skips the remaining code in a <code>do</code> , <code>for</code> , or <code>while</code> block.
defer	<code>defer <statement or statement block></code>	Adds to the code to be run before exiting the current scope.
defer:clear	<code>defer:clear;</code>	Removes all the code to be run before exiting the current scope.
defer:top	<code>defer:top <statement or statement block></code>	Adds to the top of the code to be run before exiting the current scope.
defer:undo	<code>defer:undo;</code>	Undoes the last action performed on the defer code.
do	<code>do [(<condition>)] <statement or statement block></code>	Runs code then loops as long as the condition is true and loops forever if no condition is provided.
else	<code>else <statement or statement block></code>	Can only be put after an <code>if</code> or <code>elseif</code> block and runs code if all previous conditions in the chain are false.
elseif	<code>elseif (<condition>) <statement or statement block></code>	Can only be put after an <code>if</code> or another <code>elseif</code> block and runs code if all previous conditions in the chain are false and the current condition is true.
fall	<code>fall [case value];</code>	Falls through to another case inside of a <code>switch</code> statement, falls through to <code>default</code> if there is no case for that value, and falls through to the case directly under if no case is provided.
for	<code>for (<variable declarations>; <condition>; <each-time statement or block>) <statement or block></code>	Declares the variables specified into the statement or block and for each time the condition evaluates to non-zero, runs the statement or block then the each-time statement or block.

global	global.<name>	Provides a shortcut to the global scope for use in namespaces. Is valid in all scopes.
goto	goto <name>;	Jumps to a label inside of the current function.
if	if (<condition>) <statement or statement block>	Runs code if the condition is true. Removing the brackets makes the block effective for only 1 statement after.
label	label <name>;	Creates a label in the current scope with the name given.
return	return <data>;	Returns from a function and returns data if not void.
switch	<pre> switch (<variable>) { case (<value>) { [statements] } case (<val 1>, <val 2>) { [statements] } case (<value>..<value>) { [statements] } case (<value>...<value>) { [statements] } default { [statements] } } </pre>	Compares a variable and jumps to the code at the corresponding case statement. The code at the default statement will run if provided and no case statements match. To have one case for multiple values, separate the values with commas. Placing two dots between two values will match that case for the first value and any values in-between. Placing three dots between two values will match that case for the first value, any values in-between, and the last value.
while	while (<condition>) <statement or statement block>	Loops code as long as the condition is true.

Assignment

cast	cast:<type>(<data>)	Returns data as a different type.
ternary	ternary(<condition>, <value 1>, <value 2>)	Returns value 1 if the condition is true and value 2 otherwise.

Data		
<code><cast from> :cast:<cast to></code>	<code><type(s) to cast from>:cast :<type(s) to cast to> (<input>) <statement or statement block></code>	<p>Defines code to perform a cast from a single type to a comma-separated list of types, or a comma-separated list of types to a single type. If no definite <code>return</code> is provided, then the cast is considered invalid. The input argument has the types of the first types and the return statement expects to return a value compatible with the second types (the compiler will attempt to use the code for all the combinations possible with the given types).</p> <p>Examples:</p> <pre>my_t:cast:bool(in) { return in.valid; } my_t:cast:__INT_TYPES (in) { return in.data; } __INT_TYPES:cast:my_t (in) { return {true, in}; }</pre>
<code>enum</code>	<code>enum[:<type>] [(<equation>)] { <name>[= <rhs value>]; }</code>	<p>Makes an enumerated variable list and the variables will not receive symbols. Placing an equation in parentheses with the format <code><lhs> <operator> <rhs></code> will change what is used to generate the numbers. The default is <code>0 + 0</code>. Specifying parts of the equation will only change that part. If only one value is specified, it is assumed to be the left hand side. Values are generated by incrementing the right hand side. Placing an equal sign and a value after a name will set the right hand side to that value and continue incrementing from there. If a type is specified after a colon, that type will be used instead of <code>int</code>.</p>
<code>newtype</code>	<code>newtype <name> <type></code>	<p>Creates a new type shortcut to a type.</p>
<code>sizeof</code>	<code>sizeof(<type or variable>)</code>	<p>Returns the size in bytes of a type or the type of a variable.</p>

struct structure	<pre>struct <name> { <type>[:<bits>] <name>; }</pre> <pre>struct(<name>) <variable declaration(s) or definition(s)></pre>	Creates a structure definition or variable. If a colon and number is provided a type, it will be limited to that size in bits and the compiler will attempt to pack adjacent values in the unused bits.
<type>: :default	<pre><type>:default = <value></pre>	Sets the default value for a type in the current scope. Only static values are allowed.
<type>:<op>	<pre><type>:<operation> (<var 1>, <var 2>) <statement or statement block></pre>	<p>Defines code to perform an action on a type. If no definite <code>return</code> is provided, then the operation is considered invalid. The return statement expects to return a value of the type given.</p> <p>Operations: add, and, dec, div, inc, lrot, lshift, mod, mul, or, rrot, rshift, and xor.</p> <p>Example:</p> <pre>my_t:add (op1, op2) { return op1.v + op2.v; }</pre>
typeof	<pre>typeof(<variable>)</pre>	Returns the type of the given variable.
union	<pre>union <name> { <variable declarations> }</pre> <pre>union(<name>) <variable declaration(s) or definition(s)></pre>	Creates a union definition or variable. Each value is stored at the same location and the size will be the size of the largest type at minimum.

Miscellaneous		
asm	asm[:<syntax>] (<quoted register name> <variable name to set register to>) { <assembly> } asm[:<syntax>] (<quoted register name> <variable name to set register to>) "<assembly>";	Compile assembly into the current position. If no colon and syntax name are provided, the compiler should use its default syntax. The parentheses are also optional and can be omitted if no variables are to be written to registers. For assembly code that interferes with Wizardry's characters, place the code inside quotes instead of curly braces and end with a semicolon.
attrib	attrib ([attribute(s)]) <statement or statement block>	Set attributes for a statement or statement block. Attributes are a comma-separated list of attrib = value. Attributes can only be set to static values.
vararg	vararg(<type>) vararg(<pointer>, <type>)	Returns the next argument in a variadic function. The single-argument version is invalid in functions that are not variadic. The dual-argument version expects a pointer returned by varargs() and is invalid for variadic functions.
varargs	varargs()	Returns a pointer to the head of the variadic argument data. Is invalid in functions that are not variadic.
varargct	varargct() varargct(<pointer>)	Returns the number of variadic arguments passed to the function. The version that does not accept arguments is invalid in functions that are not variadic. The single-argument version expects a pointer returned by varargs() and is invalid for variadic functions.

Modifiers		
autoinline	autoinline <function declaration and/or definition>	Makes it so a function can be embedded into where it is called from to avoid a function call and increase speed. The compiler should decide to inline or not based on what is best for performance. This is invalid on variables.

default	default <function declaration and/or definition>	Declares a variant of a function to be the default therefore giving it an unmangled symbol. Is only valid if the overload pragma is enabled. Can only be used on one variant per function.
dynamic	dynamic <function declaration and/or definition>	Allows a function's address to be changed.
extern external	extern <variable declaration(s) and/or definition(s)>;	Declares a variable that is stored outside the current file and is invalid on functions.
inline	inline <function declaration and/or definition>	Makes it so a function can be embedded into where it is called from to avoid a function call and increase speed. The compiler will embed whenever it can unless it goes against optimization (such as embedding large functions when optimizing for size). This is invalid on variables.
mangle	mangle <function declaration and/or definition>	Forces a function's symbol to be mangled or generates a mangled symbol if used with default. Is only valid if the overload pragma is enabled.
nooptimize	nooptimize <variable declaration(s) and/or definition(s), or function declaration and/or definition>	Makes a variable or function ineligible for optimization.
private	private <function declaration and/or definition>	Makes it so a function or variable is not visible outside of the current file or namespace shard.
reg register	reg <variable declaration(s) and/or definition(s)>;	Recommends that the compiler use a register to hold the data and is invalid on functions.
static	static <variable declaration(s) and/or definition(s)>	Makes a local variable hold its value after exiting its scope and is invalid on functions.

Compiler

Compiler requirements:

- The ability to compile multiple files
- The ability to change the output target
- The ability to skip the linking stage and output object files
- The ability to output a linked executable
- Order-independent linking
- A way to define macros outside of source files (preferably using a command-line switch)
- A way to output a list of files included in the provided source files with the ability to change whether system headers are included in the output and change whether relative or absolute paths are used (preferably using a command-line switch)
- A way to add directories to search for includes outside of source files (preferably using a command-line switch)
- A way to add directories to search for libraries outside of source files (preferably using a command-line switch)
- A way to output a list of default compiler macros and the values of those macros (preferably using a command-line switch)
- A way to output a list of macros defined in the provided source files (preferably using a command-line switch)

Preprocessor commands and functions:

In order for a line to be recognized as a preprocessor command, the first non-whitespace character must be an at symbol (@).

Preprocessor commands end after a newline.

To continue a command past a newline, insert a backslash before the newline.

Preprocessor commands can only accept static values unless stated otherwise.

The compiler must support at least 10 nested comments.

Comments started with #< must end with #> and comments started with /* must end with */.

# //	# <text> // <text>	Comment until end of line.
#< /*	#< <text> <text> <text> #> #< <text> #> /* <text> <text> <text> */ /* <text> */	Start a comment.
#> */	#< <text> <text> <text> #> #< <text> #> /* <text> <text> <text> */ /* <text> */	End a comment.
error	@error "<string>"	Raises a compiler error using the provided string as or in the message.
else	@else <statements>	Exposes the statements provided if the above <code>elseif</code> or <code>if</code> command is false.
elseif	@elseif <condition> <statements>	Exposes the statements provided if the condition is true and the above conditional command is false.
elseifdef	@elseifdef <macro names> <statements>	Exposes the statements provided if the provided macro names are defined and the above conditional command is false. The <code> </code> , <code>&&</code> , and <code>!</code> operators along with parentheses can be used to test multiple names.

endif	@endif	Ends an if command.
def define	@define <macro name> <text>	Defines a macro as the text provided.
defined	defined(<macro name>)	Returns (1) if a macro is defined and (0) otherwise.
defifndef	@defifndef <macro name> <statements>	Defines a macro as the text provided if it is not already defined.
if	@if <condition> <text>	Exposes the statements provided if the condition is true.
ifdef	@ifdef <macro names> <statements>	Exposes the statements provided if the provided macro names are defined. The , &&, and ! operators along with parentheses can be used to test multiple names.
include	@include <file name>	Includes a file onto the current line. <file>: Include file from the standard include directory. If no file extension is provided, search for the file name and if there is no match, search for the file name with .wh added. If given a directory, all .wh files in the first level will be included. [file]: Solve the file name as a filename regular expression and include it from the standard include directory. 'file': Include file relative to the current file's location. If no file extension is provided, search for the file name and if there is no match, search for the file name with .wh added. If given a directory, all .wh files in the first level will be included. "file": Solve the file name as a filename regular expression and include it relative to the current file's location.
pragma	@pragma <command>	Sends a command to the compiler.
warning	@warning "<string>"	Raises a compiler warning using the provided string as or in the message.

Pragmas:

Compiler pragmas only have effect on the current file unless stated otherwise. Meaning that for example, unless stated otherwise in the command description, pragma commands in an included file will not effect the file it was included from unless specified otherwise.

<code>lazybool</code>	<code>lazybool <true/yes, false/no, or no value></code>	Causes <code>bool</code> to not guard against becoming greater than 1 or less than 0. This is false by default. Providing no value will assume <code>true</code> .
<code>moreinline</code>	<code>moreinline <true/yes, false/no, or no value></code>	Causes <code>autoinline</code> to behave like <code>inline</code> .
<code>overload</code>	<code>overload <true/yes, false/no, or no value></code>	Allows function overloading and enables function name mangling for overloaded functions. This is false by default. Providing no value will assume <code>true</code> .
<code>smallbool</code>	<code>smallbool <true/yes, false/no, or no value></code>	Causes <code>bool</code> become the same size as <code>char</code> instead of the same size of <code>int</code> . This is false by default. Providing no value will assume <code>true</code> .
<code>var</code> <code>variable</code>	<code>var <comma separated list of <var = val>></code>	Sets internal compiler variables.
<code>initvar</code>	<code>initvar <true/yes, false/no, or no value></code>	Causes local variables to be set to the default value for their type instead of uninitialized when no initial value is given. This is true by default. Providing no value will assume <code>true</code> .
<code>...</code>	<code>...</code>	Compiler-specific commands can be added.

Macros:

All compiler-defined macros except `NULL`, `true`, and `false`, should start with two underscores. The compiler should not define any functions or variables.

Macros take precedence over functions and variables. For example, defining the variable `TEST` and defining a macro `TEST` in the same program will use the macro instead of the variable. It is recommended that the compiler throw a warning about conflicts like this.

<code>__ARCH_<name></code>	<p>Name of the CPU architecture(s) the compiler is targeted at. If the architecture has multiple names, most known names and combinations should be available.</p> <p>Examples:</p> <pre>__ARCH_x86_64 __ARCH_amd64 __ARCH_AMD64</pre> <p>or</p> <pre>__ARCH_x86 __ARCH_i386</pre> <p>or</p> <pre>__ARCH_ARM __ARCH_ARM32 __ARCH_AARCH32 __ARCH_AArch32</pre>
<code>__ASM_DEFAULT_<name></code>	<p>Name of the assembly syntax or assembly compiler the compiler uses by default.</p> <p>Example:</p> <pre>__ASM_DEFAULT_ATT</pre>
<code>__ASM_HAS_<name></code>	<p>Name of the assembly syntax(s) or assembly compiler(s) the compiler supports. For general syntax support, the macro should use the name of the syntax. For support of a specific compiler, the macro should use the compiler's name.</p> <p>Examples:</p> <pre>__ASM_HAS_GAS __ASM_HAS_ATT __ASM_HAS_INTEL __ASM_HAS_NASM</pre>
<code>__COMPILER <name></code>	<p>Name of the compiler in an 8-bit ASCII string.</p> <p>Example: "Wizard"</p>
<code>__COMPILER_BUILD <number></code>	<p>Build or version number of the compiler.</p> <p>Example: 1002010</p>

<code>__COMPILER_BUILD_STRING</code> <string>	Build or version of the compiler in a string format. Example: "1.2.10"
<code>false (0)</code>	A value that evaluates as false.
<code>__FILE</code>	A macro containing the name of the current file contained in a string. Example: "hello.wiz"
<code>__FILE_PATH</code>	A macro containing the file path given to the compiler. Example: "src/hello.wiz"
<code>__FUNCTION</code>	A dynamic macro containing the name of the current function contained in a string. When used globally, the string should be empty. Example: "main"
<code>__FLOAT_TYPES</code>	A comma-separated list of floating-point type names supported by the compiler. This should always include all variations of the <code>float</code> base type and any of the base types starting with <code>f</code> . This should not include optional types.
<code>__INT_TYPES</code>	A comma-separated list of integer type names supported by the compiler. This should always include all variations of the <code>int</code> and <code>char</code> base types and any of the base types starting with <code>i</code> or <code>u</code> . This should not include optional types.
<code>__LINE</code>	A dynamic macro containing the line in the file that this macro was used. Example: 47
<code>__NAMESPACE</code>	A dynamic macro containing the name of the current namespace contained in a string. When used outside of any namespaces, the string should be empty. Example: "funcs"
<code>__NAMESPACE_TREE</code>	A dynamic macro containing the current namespace tree contained in a string. When used outside of any namespaces, the string should be empty. Example: "mylib.io.funcs"
<code>NULL</code>	A null pointer. This should be <code>(cast:void\$(0))</code> for most platforms. For platforms that do not use zero to indicate a null pointer, only the number should be changed.

<code>__OPTIONALTYPE_<name></code>	<p>Defined if the compiler supports an optional type with this name.</p> <p>Example: <code>__OPTIONALTYPE_dec64</code></p>
<code>__OS_<name></code>	<p>Name of the operating system the compiler is targeted at in capital letters. If the operating system has multiple names or terms, most known names and combinations should be available.</p> <p>Examples:</p> <p><code>__OS_LINUX</code> <code>__OS_UNIX</code> or <code>__OS_BSD</code> <code>__OS_FREEBSD</code> <code>__OS_UNIX</code> or <code>__OS_WINDOWS</code> <code>__OS_WINDOWS_NT</code> or <code>__OS_WINDOWS</code> <code>__OS_WINDOWS_9X</code></p>
<code>__STANDARD <version></code>	<p>Version number of the Wizardry standard the compiler supports.</p> <p>Example: 2022121600</p>
<code>true (1)</code>	A value that evaluates as true.

Grammar

Grammar syntax:

* :: Root definition

:: Make definition

<>: Insert definition

() : Group

[] : Optional group or definition

{ } : Choice

\\ : Description

`` : Interpreted string (supports backslash escaped characters)

` ` : Literal string

// : Regular expression (must match from start to end of input to be considered a match)

| : Or

... : Continue

* :

Standard Library

All standard library functions, variables, and type definitions should be held in the `wiz` namespace.

Standard library headers should be split into separate headers under `wizardry/*.wh`.

Any variables, enums, functions, types, or defines in the standard library that are not part of the specification should start with a single underscore.

Macros and variables missing a value next to them are defined based on implementation.

All standard library functions should guard against `NULL` unless specified otherwise.

Headers:

wizardry/	
Variables	
Enumerators	
Functions	
Types	
Macros	

wizardry/io.wh	
Variables	
<code>wiz.file wiz.in</code>	Input stream file pointer.
<code>wiz.file wiz.out</code>	Output stream file pointer.
<code>wiz.file wiz.err</code>	Error stream file pointer.
<code>int wiz.infd</code>	Input stream file descriptor.
<code>int wiz.outfd</code>	Output stream file descriptor.
<code>int wiz.errfd</code>	Error stream file descriptor.
Functions	

<code>int wiz.close(int fd)</code>	<p>Close a file stream using a descriptor. Returns 0 on success and a negative error code on failure.</p> <p><code>fd</code>: File descriptor to close.</p>
<code>int wiz.fclose(wiz.file\$ file)</code>	<p>Close a file structure by closing the stream with <code>close</code> and deallocating the structure using <code>free</code>. Returns 0 on success and a negative error code on failure.</p> <p><code>file</code>: File structure to close.</p>
<code>int wiz.fdprint(int fd, char\$ text)</code>	<p>Writes a string to a file descriptor. Returns the a negative error code on failure to write all bytes and the number of bytes written otherwise.</p> <p><code>fd</code>: File descriptor. <code>text</code>: String to write.</p>
<code>int wiz.fdputc(int fd, char chr)</code>	<p>Writes a char to a file descriptor. Returns 0 on success and a negative error code on failure.</p> <p><code>fd</code>: File descriptor. <code>chr</code>: String to write.</p>
<code>int wiz.fdprintf(int fd, char\$ text, ...)</code>	<p>Writes a formatted string to a file descriptor. Returns the a negative error code on failure to write all bytes and the number of bytes written otherwise.</p> <p><code>fd</code>: File descriptor. <code>text</code>: String to write. <code>...</code>: Variadic arguments for format.</p>
<code>int wiz.flush(wiz.file\$ file)</code>	
<code>wiz.file\$ wiz.fopen(char\$ path, char\$ mode, int\$ err)</code>	<p>Uses <code>open</code> to open a file descriptor and returns a pointer to a file structure dynamically allocated using <code>alloc</code>. Returns a valid pointer on success and on failure, returns <code>NULL</code> and sets <code>err</code> to an error code if not <code>NULL</code>.</p> <p><code>path</code>: File path. <code>mode</code>: File mode string. <code>error</code>: Pointer to output error code.</p>
<code>int wiz.fprint(wiz.file\$ file, char\$ text)</code>	<p>Writes a string to a file type. Returns the a negative error code on failure to write all bytes and the number of bytes written otherwise.</p> <p><code>file</code>: File type <code>text</code>: String to write.</p>

<code>int wiz.fputc(wiz.file\$ file, char char)</code>	Writes a char to a file type. Returns 0 on success and a negative error code on failure. file: File type chr: String to write.
<code>int wiz.fprintf(wiz.file\$ file, char\$ text, ...)</code>	Writes a formatted string to a file type. Returns the a negative error code on failure to write all bytes and the number of bytes written otherwise. file: File type text: String to write. . . .: Variadic arguments for format.
<code>int wiz.open(char\$ path, char\$ mode)</code>	Opens a file stream using the lowest possible non-negative descriptor. Opening the same file will return a new descriptor. Returns a descriptor on success and a negative error code on failure. path: File path. mode: File mode string.
<code>int wiz.print(char\$ text)</code>	Writes a string to the output file stream. Returns the a negative error code on failure to write all bytes and the number of bytes written otherwise. text: String to write.
<code>int wiz.putc(char chr)</code>	Writes a char to the output file stream. Returns 0 on success and a negative error code on failure. chr: String to write.
<code>int wiz.printf(char\$ text, ...)</code>	Writes a formatted string to the output file stream. Returns the a negative error code on failure to write all bytes and the number of bytes written otherwise. text: String to write. . . .: Variadic arguments for format.
Types	
<code>wiz.file</code>	Implementation-specific.
Macros	
<code>wiz.IN_FILENO</code>	Input stream file number.
<code>wiz.OUT_FILENO</code>	Output stream file number.
<code>wiz.ERR_FILENO</code>	Error stream file number.

wizardry/dynlib.wh	
Functions	
<code>void wiz.freelib(wiz.dynlib\$ lib)</code>	<p>Closes and frees a dynamic library.</p> <p><code>lib</code>: Pointer returned by <code>loadlib</code>.</p>
<code>int wiz.freesym(wiz.dynlib\$ lib, char\$ name)</code>	<p>Frees a symbol from memory. Any calls to the pointer returned by <code>getsym</code> will result in undefined behavior. Returns 0 on success and a negative error code on failure.</p> <p><code>lib</code>: Pointer returned by <code>loadlib</code>. <code>name</code>: Symbol name</p>
<code>void\$ wiz.getsym(wiz.dynlib\$ lib, char\$ name, int\$ err)</code>	<p>Returns the pointer to a symbol from a library. Sets <code>err</code> to an error code if not <code>NULL</code> and returns <code>NULL</code> if not successful.</p> <p><code>lib</code>: Pointer returned by <code>loadlib</code>. <code>name</code>: Symbol name</p>
<code>wiz.dynlib\$ wiz.loadlib(char\$ path, int options, int\$ err)</code>	<p>Opens a dynamic library and returns a pointer to be used with other functions. Searches system library directories by default (<code>/lib</code> and/or <code>/usr/lib</code> on Unix-based operating systems for example). Sets <code>err</code> to an error code if not <code>NULL</code> and returns <code>NULL</code> if not successful.</p> <p><code>path</code>: Path or filename of the library file. <code>options</code>: Option flags for finding or loading the library. Combine flags with the bitwise OR operator.</p>
<code>char\$ wiz.mangle(char\$ ret, char\$ name, char\$\$ args, int\$ err)</code>	<p>Produces a mangled symbol name from info about a function. The return value should be freed by the caller. <code>NULL</code> is returned on failure and <code>err</code> is set if not <code>NULL</code>.</p>
<code>int wiz.mangleto(char\$ out, luint size, char\$ ret, char\$ name, char\$\$ args)</code>	<p>Writes a mangled symbol name to a string using info about a function. On failure, a negative error code is returned and <code>out</code> is left unmodified. On success, the length of the string not including the terminator is returned.</p>
Types	
<code>wiz.dynlib</code>	Implementation-specific.
Macros	
<code>wiz.DYNEXT</code>	<p>File extension of shared libraries native to the target operating system or architecture.</p> <p>Examples: <code>".so"</code> <code>".dll"</code></p>

<code>wiz.DYN_SEARCH_LOCAL</code>	Search in the local directory instead of the system library paths.
<code>wiz.DYN_LOAD_LAZY</code>	Load in only the parts of the library requested instead of the whole library. This will increase the time it takes to get a symbol but will save memory.
<code>wiz.DYN_...</code>	Other operating system or architecture specific flags can be added.

wizardry/memory.wh	
Functions	
<code>void\$ wiz.alloc(luint size)</code>	<p>Dynamically allocate a block of memory on the heap. Returns a valid pointer on success and on failure, returns <code>NULL</code> if not successful.</p> <p><code>size</code>: Size in bytes of how large the block should be.</p>
<code>luint wiz.asize(luint size)</code>	<p>Align a size to the size of a machine word.</p> <p><code>size</code>: Size to align.</p>
<code>void wiz.copymem(void\$ src, void\$ dest, luint len)</code>	<p>Copies a certain amount of bytes from a memory pointer to another without overwrite errors. This function should not guard against <code>NULL</code>.</p> <p><code>src</code>: Pointer to memory to reading from. <code>dest</code>: Pointer to memory to start writing at. <code>len</code>: Amount of bytes to copy.</p>
<code>void wiz.fillmem(void\$ ptr, luint len, u8 value)</code>	<p>Writes a certain amount of bytes at a memory pointer. This function should not guard against <code>NULL</code>.</p> <p><code>ptr</code>: Pointer to memory to start writing at. <code>len</code>: Amount of bytes to write. <code>value</code>: Value to write.</p>
<code>void wiz.free(void\$ ptr)</code>	<p>Free a dynamically allocated block of memory returned by <code>alloc</code>.</p> <p><code>ptr</code>: Pointer to the block of memory to be freed.</p>
<code>void\$ wiz.realloc(void\$ ptr, luint size)</code>	<p>Reallocates or resizes a dynamically allocated block of memory returned by <code>alloc</code>. Returns a valid pointer on success and <code>NULL</code> on failure. Should behave as <code>alloc</code> if given <code>NULL</code>.</p> <p><code>ptr</code>: Pointer to existing memory block. <code>size</code>: New size.</p>

<pre>private inline luint wiz.iasize(luint size)</pre>	<p>Align a size to the size of a machine word. This function should be written in the header.</p> <p>size: Size to align.</p>
<pre>private inline void wiz.icopymem(void\$ src, void\$ dest, luint len)</pre>	<p>Copies a certain amount of bytes from a memory pointer to another without overwrite errors. This function should not guard against <code>NULL</code>. This function should be written in the header.</p> <p>src: Pointer to memory to reading from. dest: Pointer to memory to start writing at. len: Amount of bytes to copy.</p>
<pre>private inline void wiz.ifillmem(void\$ ptr, luint len, u8 value)</pre>	<p>Writes a certain amount of bytes at a memory pointer. This function should not guard against <code>NULL</code>. This function should be written in the header.</p> <p>ptr: Pointer to memory to start writing at. len: Amount of bytes to write. value: Value to write.</p>
<pre>private inline void wiz.izeromem(void\$ ptr, luint len)</pre>	<p>Writes a certain amount of zeros at a memory pointer. This function should not guard against <code>NULL</code>. This function should be written in the header.</p> <p>ptr: Pointer to memory to start writing at. len: Amount of zeros to write.</p>
<pre>void\$ wiz.valloc(luint size, u8 value)</pre>	<p>Calls <code>alloc</code>, sets the bytes in the memory block returned to a value if <code>alloc</code> returns a valid pointer, and returns the output of <code>alloc</code>.</p> <p>size: Size in bytes of how large the block should be. value: Value to set each byte to.</p>
<pre>void\$ wiz.zalloc(luint size)</pre>	<p>Calls <code>alloc</code>, zeros the memory block returned if <code>alloc</code> returns a valid pointer, and returns the output of <code>alloc</code>.</p> <p>size: Size in bytes of how large the block should be.</p>
<pre>void wiz.zeromem(void\$ ptr, luint len)</pre>	<p>Writes a certain amount of zeros at a memory pointer. This function should not guard against <code>NULL</code>.</p> <p>ptr: Pointer to memory to start writing at. len: Amount of zeros to write.</p>
Macros	
<pre>wiz.FREE_SAFE_INVALID</pre>	<p>Defined if the <code>free</code> implementation is protected against invalid pointers.</p>

<code>wiz.REALLOC_SAFE_INVALID</code>	Defined if the <code>realloc</code> implementation is protected against invalid pointers.
---------------------------------------	---

wizardry/exit.wh	
Variables	
<code>func: void(int) wiz.atexit = NULL</code>	If non-NULL, <code>wiz.exit</code> will call this before cleaning up and exiting. The <code>int</code> argument passed to the function is the exit code.
Functions	
<code>default void wiz.exit(int code)</code> <code>void wiz.exit()</code>	Cleans up and exits the program with a code. Only the first definition is available to programs without overloading enabled. The second definition will assume the return code to be 0.
Macros	
<code>wiz.EXIT_SUCCESS</code>	A macro containing the success return code.
<code>wiz.EXIT_FAILURE</code>	A macro containing the failure return code.

wizardry/error.h	
Enumerators	
<code>wiz.ERR_NONE = 0</code>	An enum error code for no error.
<code>wiz.ERR_2BIG</code>	An enum error code for too many arguments.
<code>wiz.ERR_ALLOC</code>	An enum error code for a memory allocation error.
<code>wiz.ERR_ARG</code>	An enum error code for an invalid argument.
<code>wiz.ERR_BADFD</code>	An enum error code for an invalid file descriptor.
<code>wiz.ERR_BUSY</code>	An enum error code for a busy device or resource.
<code>wiz.ERR_CANCELED</code>	An enum error code for a cancelled operation.
<code>wiz.ERR_DQUOT</code>	An enum error code for an exceeded disk quota.
<code>wiz.ERR_EXIST</code>	An enum error code for a path already existing.
<code>wiz.ERR_FBIG</code>	An enum error code for a too large file.
<code>wiz.ERR_INVALID</code>	An enum error code for invalid data.
<code>wiz.ERR_ISDIR</code>	An enum error code for an unexpected directory.
<code>wiz.ERR_ISFILE</code>	An enum error code for an unexpected file.
<code>wiz.ERR_LINK</code>	An enum error code for too many symbolic link levels.
<code>wiz.ERR_MEM</code>	An enum error code for a memory allocation error.
<code>wiz.ERR_MFILE</code>	An enum error code for exceeding the open file limit.
<code>wiz.ERR_N2LONG</code>	An enum error code for a too long name.

wiz.ERR_NOEXIST	An enum error code for a nonexistent path.
wiz.ERR_NOTEMPTY	An enum error code for a non-empty directory.
wiz.ERR_NULL	An enum error code for an unexpected NULL.
wiz.ERR_OVERFLOW	An enum error code for a data overflow.
wiz.ERR_PERM	An enum error code for permission denied.
Functions	
char\$ wiz.errstr(int code)	Returns a string associated with an error code. code: Error code to get string for.

wizardry/string.h	
Variables	
Enumerators	
Functions	
private inline bool wiz.istrncmp(char\$ str1, char\$ str2)	
private inline bool wiz.istrcasecmp(char\$ str1, char\$ str2)	
bool wiz.strncmp(char\$ str1, char\$ str2)	
bool wiz.strcasecmp(char\$ str1, char\$ str2)	
char\$ wiz.strdup(char\$ str)	
int wiz.strcat(char\$ dest, luint len, char\$ src)	
Types	
Macros
